Abstract

File copying is frequently used to implement *ad hoc* management of file replicas, backups and versions. Such tasks can be assisted by appropriate applications, at the expense of introducing some restrictions to the usage patterns. In particular, this is the case of interactions involving disconnected machines and transportable media. PANASYNC tries to support these actions by introducing a set of commands for file copying and re-integration that complement the file-system commands and provide support for dependency analysis among time-stamp assisted files.

1 Introduction

User interaction with the file system is supported by command line or by graphical user interfaces, both alternatives providing standard operations such as file and directory creation, renaming, copying and removal. In their normal activity users can resort to a given operation in order to achieve different purposes. For instance, the *copy* operation can be used to create a backup of a file, to branch a project or even to substitute a file with the contents of another. Due to the simplicity of the basic operations available to the user, the underlying purpose cannot be perceived by the system. The system treats the operations indistinguishably, thus having no provision to assist the user along its tasks. Consequently the user is on its own, regarding, for instance, file version management.

The common solution to this problem is to adopt version-control environments offering a special set of tools and often embedding their own filing structures in the underlying file system. However, the adoption of a special environment for versioning control is usually a matter of complexity assessment, and users tend to avoid it when they want to manage what they perceive as a simple file duplication or versioning task. Few users resort to versioning support tools when taking a draft document copy to eventually work on it in a weekend.

Additionally, the use of existing versioning and replication environments calls for a centralized or at least pre-set distributed configuration that is frequently inadequate to the user mobility needs. Missing features encompass the uncoordinated creation of new replicas and isolated forking of new versions. Together these restrictions can lead users back to basic file system operations, or at least make them think twice before switching into a coordinated environment.

In this article we discuss the design of a set of tools that provide autonomous file copying and versioning. These constructs can be implemented by a set of commands that manage additional time-stamping data over an off-the-shelf file system or by the design of a file system extension that manages and hides the time-stamp data. These tools can be used as a complement to the standard file system operations.

2 Related Work

Replicated file systems such as CODA [4], FICUS [3] and RUMOR [8], are bound to rely on some notion of replication volumes (typically subtrees in a given machine). These systems can be related to version control systems if interpreted as providing version control over a well defined number of branches, when allowing optimistic replica evolution on each volume.

In these systems, the use of vector time-stamps for conflict detection requires either an indexing of the replication volumes or a way to univocally identify each volume. That assumption enables the design of file time-stamps as mappings from volume *id* (which can be a name or vector index) into an update counter [5, 7]. A consequence of this design is that a file cannot be replicated in the same volume, and in particular in the same directory.

Another problem is the transitive replication that can occur, for instance, when using transportable media. In

this case, the availability of one replica is not sufficient for the autonomous creation of the new replication volume that would host a subsequent replica. All these patterns of usage, when actually needed, lead the users back to the use of uncoordinated copy.

The solution to the autonomous identity creation problem relies on a recursive construction of the new ids, in the presence of a single file replica. The BAYOU system [6] uses a similar technique for volume identity creation. PANASYNC will use a recursive technique that is based on previous work on autonomous causality [2] and autonomous file time-stamping [1] in order to provide single file replication and versioning.

Simple but well deployed forms of replication systems, such as Microsoft Windows Briefcase and the new off-line files and folders of Windows 2000, target optimistic replication between a mobile unit (or an instance of transportable media) and one host. This restricted form of replication fits the general case of replicated file systems.

Traditional versioning systems, such as CVS[1] and PRCS[2], are targeted to manage short derivations from a central branch of development. In this sense they support an arbitrary number of concurrent evolutions but do not treat them as first class elements, and keep a centralized control on the versioning information. A recent trend in versioning systems, as depicted in BITKEEPER[3] design, aims to support parallel lines of development that share code improvements with a more robust 'diffing' technique. This approach differs from the PANASYNC scenario as it targets the management of sets of files (repositories), in contrast with a file based approach, and focuses on 'diff' portability and not on causality based domination analysis between parallel evolutions. Nevertheless this trend appears to share common motivation with our approach whilst at a different level.

3 Revisiting Copy Constructs

PANASYNC intends to add file based replication and versioning constructs in a way that complements the usual file manipulation constructs. Since some of their functionality will be complemented, it is important to review the possible applications of existing operations. Considering the arbitrary syntax and Unix mapping shown in Table 1, we discuss how some user tasks expressing replication or versioning are typically performed.

If the intent is to create a new file unrelated to the other files, the operation could be *create(content,new-file-name)*. However, it is sometimes useful to start the new file with the content of another file (for instance when starting a new LaTeX document or a CGI script), which would lead to *copy(file-name,new-file-name)*.

create(body,target)
`echo "`*body*`" > `*target*
copy(base,target)
`cp` *base target*
move(base,target)
`mv` *base target*

Table 1: Classic file constructs.

When the intent is to keep a backup copy of a given file, the operation is something like *copy(file-name,file-name.orig)* or slightly different, *copy(file-name,file-name.v01)*, if several backup versions are to be created. If, latter on, the user wants to discard changes he issues something like *copy(file-name.orig,file-name)*. Alternatively if the user needs backup versions for a set of files, he might make use of a new sub-directory that gathers a given version of the files, and then use something like *copy(*,dir-name.v01)*, which keeps the original file names but places them in a different name space.

Finally, when the intent is to replicate a file or set of files the practice is to keep the names and copy them into a different name space (disk and directory). Later on, replica identification and the possibility of replica reintegration must be evaluated by the user and lead to the appropriate *copy* or *move* operations.

In all these tasks the copy operation is heavily used and its different intents are only vaguely captured by the choice of names and name spaces that the user conducts. There is no way of providing system support to these operations and the users are on their own to make either correct decisions or mistakes.

Its is also clear that the directory structure is used for several purposes, division of name space, classification, and identification of different physical storage devices. It can be the case that files like `/floppy/panasync.tex` and `/home/cbm/psart.tex` are versions of the same entity and `/src/q/readme.txt` and `/tmp/qinst/readme.txt` are totally unrelated.

4 Panasync Operations

In order to assist file replication and versioning tasks, we propose a set of commands that track dependencies between versions of files. A file system with PANASYNC extensions, or user level commands, manages ordinary as well as panasync-enabled files, the latter having an extra time-stamp attribute. For convenience of discourse we designate the panasync-enabled files *pfiles* and the others *ofiles* (ordinary files); we also use the term *file* to

[1] `http://www.sourcegear.com/CVS/`
[2] `http://www.xcf.berkeley.edu/~jmacd/prcs.html`

new([base],target)
`pananew` *base target*
duplicate(base,target)
`panadup` *base target*
join(base,target)
`panajoin` *base target*

Table 2: Some PANASYNC constructs.

refer to either class. The traditional commands apply to both file types, but pfiles can also be manipulated by the PANASYNC operations as shown in Table 2 (where we also present possible Unix mappings).

The *new* operation is used to create a pfile. Its name, *target*, is mandatory and an optional file name for initialization is allowed by indicating a *base* file. Usage of this operation means that new a lineage of files is being created and that the target pfile is not comparable with other lineages. Ordinary files are all non comparable.

When a backup, versioning or replication action is needed, users can resort to the *duplicate* operation. This operation creates a *target* pfile from the *base* pfile and ensures that both share the same lineage. After duplication both pfiles are equivalent, hold the same contents and should be regarded as siblings. In fact, although *base* was the starting point they do not hold a parent/child relation.

An immediately subsequent *join* operation with one of these pfiles as *base* and the other as *target* would remove *base* since the system detects that they share unchanged content, as well as positions that can be determined to be equivalent in the version lineage.

By consulting the pfiles time-stamps the *join* operation is able to relate any pair of files, verify if one of the following conditions holds, and advise appropriate action:

- **Condition**: *base* and *target* are in distinct lineages, or one or both of them are ofiles.
  Action: Abort the *join* and do nothing.
- **Condition**: *base* dominates *target*, or *target* dominates *base*.
  Action: The normal action is to remove *base* and place in *target* the content that dominates (either from *base* or *target*), but an option can be provided to choose the dominated content.
- **Condition**: Neither *base* nor *target* dominates, which means that they hold concurrent updates.
  Action: Do nothing or prompt the user for a reconciliation file, in which case both *base* and *target* are removed and the new contents are stored in the position *target*. This new file dominates all files that is ancestors would dominate.

This description shows that names are not important in these operations since pfiles have enough information to distinguish file instances as well as to compare them. As a consequence of this, the choice of pfile names need only address name clash avoidance in the directory system that stores them.

In fact it is possible to design an option that applies a *join* operation recursively to two whole subtrees. This would select all pfiles from the subtrees, produce two flat lists of files and compare those in the same lineage, removing, for instance, the dominated files from the first subtree.

Another useful construct, although not a basic one, is a `panasync` *base1 base2* command that produces a *join* of the two files in a temporary pfile and immediately duplicates it again into *base1* and *base2*. The overall effect is to keep two copies with synchronized contents.

Renaming pfiles can be done as usual with the original *move* command, as long as time-stamp association to file name can be tracked. Depending on the system, this need can lead to a simple patch to the native *move* command or to the introduction of a `panamv` construct.

Finally, the use of the native *copy* with a pfile as *base* produces a *target* ofile with unrelated lineage, which is a useful functionality.

5 Synopsis of Time-Stamping

The complex pattern of version and lineage control can only be achieved with a sound time-stamping technique that supports autonomous creation of a partial order among file replicas, and the identification of lineages. A presentation of the causality model and time-stamping technique is beyond the scope of this paper. Some insight on the technique can be found in [2, 1]. Here we will only address some significant points that characterize this time-stamp model.

Vector time-stamps, as originally shown in [5], allow the tagging of identical replicas with identical time-stamps. This is possible due to the fact that the identity of the replication volumes, and the information of the hosting volume for each replica, can complement the information stored in the time-stamp. On the contrary, if we wish to have autonomous time-stamps all the relevant information must be stored in each replica time-stamp. This leads to the existence of distinct time-stamps that identify equivalent replicas. The partial order algorithm must detect that simple replica duplication does not make them different but only raises the possibility of separate modifications. Such replicas cease to be equivalent once they suffer changes.

Unlike vector time-stamps, this scheme does not impose structural limits on the number of replicas, since

replica identity is recursively constructed with the information that is locally available.

6 Example Scenarios

```
.... Setup .....

1$ pananew mybibs.bib pana.bib
2$ panadup pana.bib /floppy/pana.bib
3$ cat entry1.bib >> /floppy/pana.bib
4$ panadup /floppy/pana.bib /zip/p.bib

.... 1st Scenario ....

5$ mv /floppy/pana.bib /floppy/panasync.bib
6$ cat DSM.bib >> /zip/p.bib
7$ panajoin pana.bib /zip/p.bib
Info: /zip/p.bib content
      dominates pana.bib
8$ panajoin /zip/p.bib /floppy/panasync.bib
Info: /zip/p.bib content
      dominates /floppy/panasync.bib

.... 2nd Scenario ....

5$ cat DSM.bib >> /zip/p.bib
6$ cat OS.bib >> /floppy/pana.bib
7$ panajoin /floppy/pana.bib /zip/p.bib
Warning: Files are concurrent
         use -s to specify substitute
8$ sdiff /floppy/pana.bib /zip/p.bib -o merge.bib
9$ panajoin /floppy/pana.bib /zip/p.bib -s merge.bib
10$ panajoin /zip/p.bib pana.bib
Info: /zip/p.bib content dominates pana.bib
```

Figure 1: Example runs with PANASYNC tools.

The example in Figure 1 (with first scenario in Figure 2) shows a hypothetical use of PANASYNC commands under the Unix environment. In the setup phase a new lineage is created together with the pfile `pana.bib` and its contents are initialized with `mybibs.bib` content (`1$`). We recall that there is no ordering relation between these two files.

Afterwards the `pana.bib` file is duplicated to a directory mapping a floppy device (`2$`) and its contents are changed with the concatenation of `entry1.bib` (`3$`). Finally this file is duplicated into `/zip/p.bib` (`4$`). We can expect that `/zip/p.bib` and `/floppy/pana.bib` are equivalent, and that both dominate the local `pana.bib` content.

For simplicity all examples have been illustrated in a single machine. It must be kept present that all operation steps are possible on any arbitrary machine that accesses the used persistent store. The use of floppy and zip names emphasizes this possibility since they designate transportable persistent media.

6.1 First Scenario

Now we change the name of the floppy resident file into `/floppy/panasync.bib` (`5$`). In fact we can *move* this file to any place or system since its identity does not depend on its name. Next we add some content to `p.bib` and try to *join* it with the local `pana.bib` (`6$`).

This *join* is straightforward since one of the files dominates the other. As usual, the two files supplied as arguments to `panajoin` are checked for their relative order and the *join* outcome is written to the second file argument. This is the case even if the second file is the dominated one.

After the last `panajoin` invocation the three replicas from the start of this first scenario have been collapsed into a single replica at `/floppy/panasync.bib`. Since there were no concurrent changes the convergence was trivially accomplished. A simple way to check for the presence of concurrent changes, in Figure 2 as well an in the second scenario figure, it to track the bullets (•) that indicate changes. This can be done by following the arrows, from the replicas, in the reverse direction and check if both have changes that the other has not seen.

6.2 Second Scenario

In this second scenario, with its evolution outline in Figure 3, we make sure that some concurrency of changes does occur, by adding content to both `/zip/p.bib` (`5$`) and `/floppy/pana.bib` (`6$`). Consequently, the *join* tentative over these two files fails and issues a warning identifying the occurrence of concurrency, and asking for the provision of a content that re-conciliates the files.

The user is free to choose the content that is to be provided. Is this case, the user resorts to the `sdiff` tool in order to select the merged content from the two concurrent files and to supply it to the next `panajoin` invocation.

The last `panajoin` invocation illustrates that when merges of concurrent evolutions occur, the order of the new pfile is such that it dominates all the pfiles that were previously dominated by either of the merged pfiles. This factor empowers the user decisions when supplying a merge and helps future replica convergence, thus constituting a very powerful property that is particular to this system.

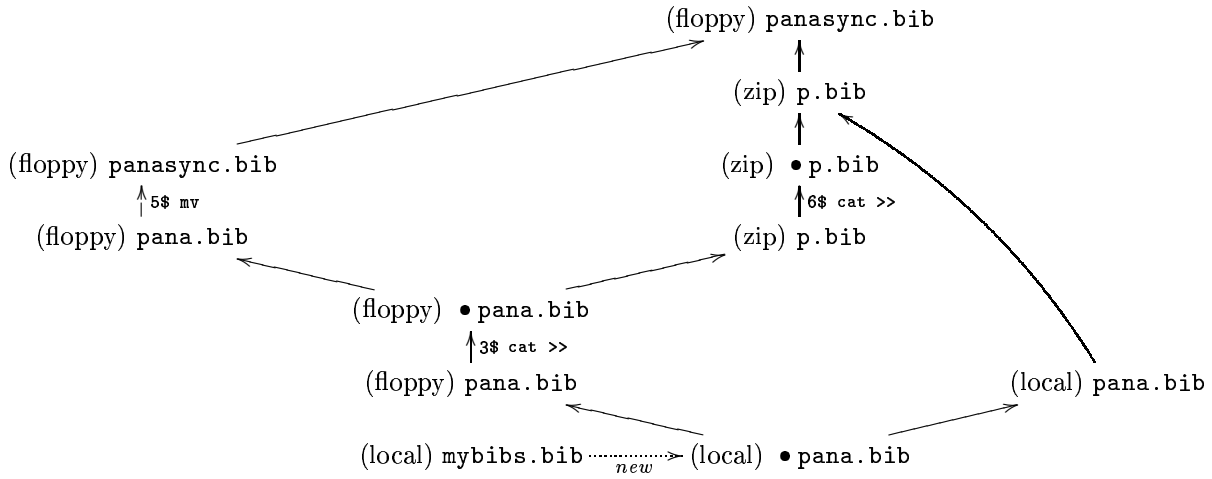

Figure 2: First Scenario. Here a single branch dominates the other branches. The `mv` action that renames one of the *pfiles* does not change its identity and time-stamp.

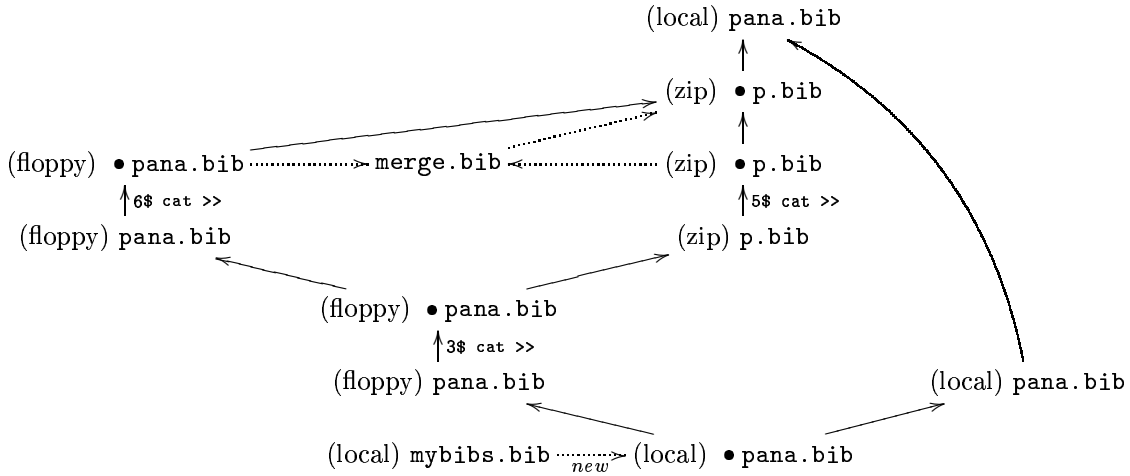

Figure 3: Second Scenario. Two parallel branches suffer concurrent changes and are re-conciliated with a merge content. The resulting *pfile* inherits existing domination relations and supersedes an early branch.

7 Design Issues

The basic PANASYNC implementation will be built over a set of portable command-line tools. The purpose of these tools is not only to test the use of this dependency tracking system, but also to ease its integration into existing file managers. A second phase will encompass the exploration of an adaptation technique for native file systems, eventually with the use of a reflection mechanism.

In PANASYNC, file naming is a user convenience although the system does not rely on it to track dependencies between pfiles. Evidences from observation of typical patterns of usage suggest that PANASYNC users should be able to change pfile names at will and the system must still be able to ensure correct dependency tracking. To achieve this purpose, PANASYNC will rely on a mapping from a special pfile identifier into its name. This will enable the system to assess if two pfiles belong to the same lineage independently of their current names. The identifier will be given to the pfile upon creation and associated to the specified name. Each time a *move* is issued the pfile identifier mapping will be updated. For practical purposes this identifier can be generated from traditional techniques based on existing hardware settings (e.g. ethernet address), file creation time and a random value.

To achieve its purposes, PANASYNC needs to store this extended information about pfiles. In fact, not only it will need to record the current name of each pfile, but also its time-stamp and an MD5 digest to actually track its dependencies.

Another issue in the design of PANASYNC is the trans-

parent detection of modification of pfiles' content. This objective cannot be reliably achieved by evaluating the creation and modification time-stamps provided by most of the traditional file systems. Instead, PANASYNC calculates a MD5 digest for each pfile upon its creation, and also stores this information on the mappings discussed above. Each time `panadup` and `panajoin` are issued the MD5 is recalculated, enabling the detection of modifications on the pfiles with the setting of a dirty attribute that is used in the time-stamp construction algorithm.

To ensure portability PANASYNC will provide an external representation of pfiles' attributes. This will enable transferring pfiles through non-supported systems, such as email, for instance.

8 Conclusions and Future Work

We have presented the motivation behind the conception of PANASYNC and shown usage scenarios. The system aims to support common tasks of file replication and versioning, which could be done either manually, without system support, or under control environments that are focused toward coarser grain scenarios. Also, these environments cannot track dependencies among an arbitrary number replicas. We believe that the addressed patterns of fine grain file copying are bound to increase with ongoing trends of increased user mobility and information sharing among mobile and fixed units. The PANASYNC approach does not intend to substitute the functionality of versioning systems or replicated file systems, but rather act as orthogonal support for a particular and common class of use cases.

Apart from the practical design issues, the central point that enables the conception of a system with these characteristics is the underlying time-stamping scheme. Presently, we have reached a time-stamp design that allows identifier simplification upon joins. This design format allows us to start the construction of the first command prototypes.

Having designed the time-stamping mechanism, the next step will be the study of time-stamp size impact on the system under an average work pattern. Although not comparable with the small size of standard time attributes we are confident that the extended control possibilities will make the use of pfiles worth in a significant set scenarios.
